ABSTRACT

Two computer programs for shuttle reentry trajectory optimization are listed and described. Both programs use the conjugate gradient method as the optimization procedure. The Phase I Program is developed in cartesian coordinates for a rotating spherical earth, and crossrange, downrange, maximum deceleration, total heating, and terminal speed and altitude are included in the performance index. The Phase II Program is developed in an Euler angle system for a nonrotating spherical earth, and crossrange, downrange, total heating, maximum heat rate, and terminal speed, altitude, and flight path angle are included in the performance index. The programs make extensive use of subroutines so that they may be easily adapted to other atmospheric trajectory optimization problems.

CHAPTER 1

INTRODUCTION

The forthcoming Space Shuttle Program will involve vehicles which possess both rocket and aircraft characteristics. Because of the interplay of gravitational, thrusting, and aerodynamic forces, the trajectories that the vehicle will fly are more complicated than the trajectories of the Saturn-Apollo class. Thus, the need exists for efficient, reliable shuttle trajectory optimization programs.

This report describes two computer programs which were generated for shuttle reentry. During the time period of this contract, the national emphasis shifted from a small, low-crossrange, straight-wing orbiter to a larger, high-crossrange, delta-wing orbiter. This definitely influences the reentry trajectory in that the straight-wing trajectory usually encounters the 3g deceleration constraint whereas the delta-wing trajectory rarely (if ever) encounters the 3g-constraint but instead has high heat-rate problems. Thus, instead of making a large cumbersome program for all possible vehicles, two programs were developed. Since the Phase II-deck was developed after the Phase I-deck, it has the advantage of some improvements learned in the development of the Phase I-program.

It has been noted by numerous investigators in the last two years that shooting (or initial Lagrange multiplier guessing) iteration schemes have been almost useless in determining shuttle reentry trajectories. There exist other techniques which might be applicable to the problem and they are briefly described below:

- 1) Classical Gradient Method: This method iterates on the total control function and does not require any second-order information (i. e., second-derivatives of the Hamiltonian). This method is well-known for having excellent properties far away from the solution, but slow convergence near the solution. With respect to boundary conditions, either penalty functions^{1*} or projections² may

*Numbers refer to listings in the References section.

be employed. A modified gradient projection approach for shuttle reentry is under development at TRW-Systems³.

- 2) Second-Order Gradient Method: This method is essentially a function space Newton's method which iterates on the total control function and requires full second-order information. The method is described in Ref.4, and a shuttle-version of the program is in use at NASA-Manned Spacecraft Center⁵. It has been found that although this program obtains accurate trajectories and control histories, the deck is difficult to work with and modify, and requires extremely long computer time.
- 3) Conjugate Gradient⁶ and Function-Space Davidon⁷ Methods: These methods iterate on the total control function and do not require any second-order information. These methods are mainly motivated by deficiencies in the classical gradient and second-order gradient (or function space Newton) methods. That is, they require only first-order information and may have better convergence characteristics near the minimum than the classical gradient method. This study involved the generation of two conjugate gradient programs. It appears that the function-space Davidon method needs further analysis before it should be employed in a shuttle computer program.
- 4) Parameter Optimization Methods: In the last decade a number of efficient parameter optimization techniques have been popularized, e.g., conjugate gradient (CG), Davidon-Fletcher-Powell (DFP) variable metric. These schemes have proven their worth, and the DFP method is probably the most popular parameter optimization scheme in use today. Both the CG and DFP methods are available in Fortran subroutines⁸. The DFP method has been applied successfully to shuttle optimization by Johnson and Kamm^{9,10}. They represent the control variables by sequences of straight line segments and then use DFP to iterate for the optimal slopes of the segments subject to continuity and inequality constraints. By computing their gradients numerically, the deck is easily modified to

include additional parameters, different vehicles, and various missions. Thus, for design purposes, this is a very efficient approach.

From the discussion above of the various approaches to shuttle optimization, it would appear at first glance that parameter optimization is the superior iterative procedure. For preliminary design this is probably the case. However, the parameter optimization approach requires either prior knowledge of approximate optimal control histories or an undeterminable amount of working time devoted to selecting workable but accurate representations for the controls. In reentry this may be especially difficult because a change in terminal boundary conditions may cause a completely different bank angle control, and in many cases the bank angle would require a large number of segments to approximate it adequately. Thus, the parameter optimization approach is by no means automatic or even desirable in some cases.

Because of the deficiencies noted above for the parameter optimization approach, the need still exists for a relatively flexible and efficient function space technique. At the present time it appears that both the projected gradient and the conjugate gradient methods are the leading candidates for such a scheme, and which scheme is best is probably problem dependent. For example, the projected gradient technique is probably best for problems which are strongly influenced by boundary conditions and do not contain singular arcs. The conjugate gradient technique is probably best for problems with singular arcs and/or problems which exhibit slow convergence near the minimum with a standard gradient technique. However, not as much work has been done with the conjugate gradient technique as the projected gradient technique, so improvements in the conjugate gradient approach are occurring more frequently than in the projected gradient method. It should be noted that the conjugate gradient and gradient projection technique have been combined¹¹, but the results were not promising. However, there may exist more efficient ways of combining the two techniques, and, thus, a "projected conjugate gradient" technique may be feasible.

CHAPTER 2

THE CONJUGATE GRADIENT METHOD

In this chapter, a tutorial treatment of the conjugate gradient method will be given in both finite- and infinite-dimensional spaces. The methods for treating inequality constraints in the programs are discussed, also.

2.1 Finite-Dimensional Conjugate Gradient Method

Consider the problem of minimizing

$$f(x_1, \dots, x_n), \quad (2.1)$$

where $x \equiv (x_1, \dots, x_n)$ is an element of a bounded, connected, open subset of R^n and $f \in C^1$. If equality and/or inequality constraints are present, it is assumed that they are incorporated into (2.1) by means of penalty functions.

Before we develop the algorithm, let us consider a few general remarks about the minimization of a quadratic function. Consider

$$q \equiv x^T A x, \quad (2.2)$$

where $x \in R^n$, A is a positive definite matrix. The contours of constant q -values are n -dimensional ellipsoids centered on the global minimum $x = 0$. In 2-space, the eccentricity of the elliptical contours is dependent upon the relative magnitudes of the eigenvalues of A ; the contours are circular if the eigenvalues are equal and the contours become more eccentric as the ratio of the eigenvalues increases from one. Of course, similar results are true in n -space.

If the contours of (2.2) are noncircular, the gradient method (with a one-dimensional search) will take an infinite number of iterates to converge to the minimum if the method does not converge on the first iterate. (If the initial guess is on a principal axis of the n -dimensional ellipsoid, then a single gradient step results in $x = 0$.) On the other hand, no matter what the eigenvalues are, Newton's method will converge in one iterate.

The reason why the quadratic problem is of interest is that in the terminal stages of an iterative minimization of many nonlinear functions, the

the function may be well-approximated by a second-order expansion. Thus, an efficient algorithm for general functions should have good convergence characteristics for quadratic functions. As noted above for quadratic functions, Newton's method is excellent in all cases, while the gradient method is strongly problem dependent. However, Newton's method requires the computation of second-order information while the gradient method requires only first-order. In addition, for general nonlinear functions, Newton's method may diverge whereas the gradient method will, at least, never result in an iterate which increases the quantity to be minimized.

Because of the properties discussed above, researchers in the 1950's attempted to develop techniques which combined the advantages of the gradient and Newton methods while minimizing their disadvantages. With respect to the quadratic minimization problem, two techniques with the following properties were developed: (i) the methods are stable, (ii) the minimum is obtained in at most n iterations, (iii) no second-order information is required. The methods are the conjugate gradient method¹² and the Davidon variable metric method¹³ (or Davidon-Fletcher-Powell¹⁴ method).

With respect to general nonlinear functions, the methods retain properties (i) and (ii) mentioned above. For certain classes of functions, rates of convergence are known for all of the methods mentioned except the DFP method. These show that when the methods work, Newton should be faster than the CG method, and the CG method should be faster than the gradient method. However, Newton's method does not possess either property (i) or (ii) mentioned above.

The CG formula will now be stated, the sequence of steps required in the development of the formula will be outlined, and then the steps will be developed in detail. The CG algorithm is as follows:

$$\begin{aligned}
 (1) \quad & \text{Guess } x_0. \text{ Define } g \equiv f_x. \\
 (2) \quad & p_0 \equiv g_0, \quad p_{J+1} = g_{J+1} + p_J \left(\frac{g_{J+1}^T g_{J+1}}{g_J^T g_J} \right) \quad (J = 0, 1, \dots). \quad (2.3)
 \end{aligned}$$

$$(3) \quad x_{J+1} = x_J - \alpha_J p_J. \quad (\alpha_J \geq 0) \quad (2.4)$$

In the formula above, x_J is an n -vector, g_J is the n -vector gradient, p_J is the n -vector search direction, and α_J is a scalar.

The formula development involves the following sequence of steps:

- (A) Assume $x_{J+1} = x_J - \alpha_J p_J$ with $p_J = g_J + b_J$, and devise a means for defining b_J .
- (B) Show that $g_J^T b_J = 0$ implies the method will be stable.
- (C) Show that the largest decrease in f is obtained if $g_{J+1}^T p_J = 0$.
- (D) Note that (B) and $b_J \equiv C_J p_{J-1}$ imply (C), where C_J is a constant to be defined.
- (E) Show that finite convergence for the quadratic function $f = x^T A x$ is guaranteed if $p_I^T A p_J = 0$ ($I \neq J$), i.e., the search directions are "A-conjugate."
- (F) Combine all of the above steps to show that

$$b_J = \langle g_J, g_J \rangle / \langle g_{J-1}, g_{J-1} \rangle p_{J-1}, \quad (2.5)$$

where $\langle g_J, g_J \rangle \equiv g_J^T g_J$ is an inner product in R^n . The inner product notation will be used from here on instead of the transpose notation.

Let us now develop the results noted in steps (A) to (F). First, we assume a form for the update formula

$$x_{J+1} = x_J - \alpha_J p_J \quad (2.6)$$

$$p_J = g_J + b_J. \quad (2.7)$$

The motivation for this form is that the method is basically a gradient method with a correction vector (i.e., b_J) which, hopefully, will aid the convergence characteristics of the gradient method in the neighborhood of the solution. The only undefined quantities in Eqs (2.6) and (2.7) are α_J and b_J . The scalar α_J will be determined by a 1-D search in each iteration, so the only quantity which must be characterized is the n -vector b_J .

PROPERTY 1: If

$$\langle g_J, b_J \rangle = 0 \quad (2.8)$$

then the method is stable.

Proof: Expand $f(x_{J+1})$ about $f(x_J)$ to first-order:

$$\begin{aligned} f(x_{J+1}) &= f(x_J) + \langle g(x_J), x_{J+1} - x_J \rangle \\ f(x_{J+1}) &= f(x_J) - \alpha_J \langle g_J, g_J \rangle - \alpha_J \langle g_J, b_J \rangle. \end{aligned} \quad (2.9)$$

For α_J small, a sufficient condition for $f(x_{J+1})$ to be less than or equal to $f(x_J)$ is $\langle g_J, b_J \rangle = 0$. ■

Note that Property 1 is a sufficient condition for stability. Thus, there exist numerous possibilities for techniques which could also be stable; one need only insure that the interaction of the two terms on the right-hand side of Eq. (2.9) be negative (when the first-order expansion is valid).

PROPERTY 2: Let α_J be the value of the search parameter which minimizes $f(x_J + \alpha p_J)$. Then,

$$\langle g_{J+1}, p_J \rangle = 0. \quad (2.10)$$

Proof: By definition of α_J :

$$\left. \frac{df}{d\alpha} \right|_{\alpha_J} = \left[\frac{\partial f^T}{\partial x_{J+1}} \frac{\partial x_{J+1}}{\partial \alpha} \right]_{\alpha_J} = \langle g_{J+1}, p_J \rangle = 0. \quad \blacksquare$$

PROPERTY 3: If Eq. (2.8) holds and

$$b_J = C_J p_{J-1} \quad (J = 1, 2, \dots) \quad (2.11)$$

(where $C_J \neq 0$ is a scalar to be defined), then Eq. (2.10) is satisfied.

Proof: By Eq. (2.8):

$$\langle g_{J+1}, b_{J+1} \rangle = 0 \Rightarrow \langle g_{J+1}, C_{J+1} p_J \rangle = 0.$$

Thus, Eq. (2.10) is satisfied when $C_{J+1} \neq 0$. ■

Because of Property 3, we shall assume that the correction vector, b_J , is linearly related to the previous search direction, i.e., we shall assume that b_J is defined by (2.11). In this case, the only thing that remains is the characterization of the constant C_J .

PROPERTY 4: Consider $f = \mathbf{x}^T \mathbf{A} \mathbf{x}$, where \mathbf{A} is positive definite. If the search directions are \mathbf{A} -conjugate (i. e., $\mathbf{p}_I^T \mathbf{A} \mathbf{p}_J = 0$, $I \neq J$) and Eqs. (2.6) and (2.10) hold (or, equivalently, (2.6), (2.8), (2.11)), then the global minimum $\mathbf{x} = 0$ of f is obtained in at most n iterations.

Proof: At the unique global minimum of f , the gradient $\mathbf{g} = \mathbf{A} \mathbf{x}$ must equal zero. If in the application of the algorithm either $\mathbf{g}_0, \mathbf{g}_1, \dots$, or $\mathbf{g}_{n-1} = 0$, then the property is proved. Thus, assume $\mathbf{g}_0, \dots, \mathbf{g}_{n-1} \neq 0$. At each iterate, we have

$$\mathbf{g}_J = \mathbf{A} \mathbf{x}_J. \quad (2.12)$$

By repeated use of Eq. (2.6) we have:

$$\mathbf{x}_n = \mathbf{x}_{J+1} + \sum_{i=J+1}^{n-1} \alpha_i \mathbf{p}_i$$

for any $J \in \{0, \dots, n-2\}$. From Eq. (2.11):

$$\mathbf{g}_n = \mathbf{g}_{J+1} + \sum_{i=J+1}^{n-1} \alpha_i \mathbf{A} \mathbf{p}_i. \quad (2.13)$$

The inner product of \mathbf{g}_n and \mathbf{p}_J is

$$\langle \mathbf{g}_n, \mathbf{p}_J \rangle = \langle \mathbf{g}_{J+1}, \mathbf{p}_J \rangle + \sum_{i=J+1}^{n-1} \alpha_i \langle \mathbf{p}_i, \mathbf{A} \mathbf{p}_J \rangle. \quad (2.14)$$

The first term in this equation vanishes because of Eq. (2.10), and the summation vanishes because of the \mathbf{A} -conjugacy property. Thus,

$$\langle \mathbf{g}_n, \mathbf{p}_J \rangle = 0. \quad (J = 0, 1, \dots, n-2) \quad (2.15)$$

By Eq. (2.10) we also have

$$\langle \mathbf{g}_n, \mathbf{p}_{n-1} \rangle = 0. \quad (2.16)$$

Equations (2.15) and (2.16) may be written in matrix form as

$$[\mathbf{p}_0 \mathbf{p}_1 \dots \mathbf{p}_{n-1}] \mathbf{g}_n = 0. \quad (2.17)$$

It can be shown that n \mathbf{A} -conjugate vectors are linearly independent (note that \mathbf{A} -conjugate is a generalization of orthogonality), and thus, Eq. (2.17) implies

$$g_n = 0. \quad \blacksquare \quad (2.18)$$

We now have enough information to define the constant C_J in Eq. (2.11).

PROPERTY 5: Consider $f = x^T A x$, where A is positive definite. If: the update formula is defined by Eqs. (2.6) and (2.11), the search directions are A -conjugate, and α_J and C_J are chosen to give the maximum decrease in the function f , then

$$C_J = \langle g_J, g_J \rangle / \langle g_{J-1}, g_{J-1} \rangle. \quad (2.19)$$

Proof: At a given iteration f is given by

$$f[x_J + \alpha_J g_J + \alpha_J C_J p_{J-1}].$$

At a minimum of f with respect to α_J , C_J :

$$f_{\alpha_J} = 0 \Rightarrow \langle g_{J+1}, p_J \rangle = 0 \quad (2.20)$$

$$f_{C_J} = 0 \Rightarrow \langle g_{J+1}, p_{J-1} \rangle = 0. \quad (2.21)$$

Expansion of Eq. (2.20), noting $g_{J+1} = g_J + \alpha_J A p_J$, $p_J = g_J + C_J p_{J-1}$, gives

$$\langle g_J, g_J \rangle + C_J \langle p_{J-1}, g_J \rangle + \alpha_J \langle p_J, A p_J \rangle = 0,$$

which implies

$$\alpha_J = -\langle g_J, g_J \rangle / \langle p_J, A p_J \rangle. \quad (2.22)$$

Before we obtain the desired result, note that Eqs. (2.20) and (2.21) imply

$$\langle g_{J+1}, g_J \rangle = 0. \quad (2.23)$$

To obtain the expression for C_J , we first form the inner product of $g_J = p_J - C_J p_{J-1}$ with $A p_{J-1}$:

$$\langle g_J, A p_{J-1} \rangle = \langle p_J, A p_{J-1} \rangle - C_J \langle p_{J-1}, A p_{J-1} \rangle. \quad (2.24)$$

The first inner product on the right vanishes because of A -conjugacy. The desired result is obtained by substituting $(g_J - g_{J-1})/\alpha_{J-1}$ for $A p_{J-1}$ on the left and $\langle g_{J-1}, g_{J-1} \rangle / \alpha_{J-1}$ for $-\langle p_{J-1}, A p_{J-1} \rangle$ on the right:

$$\langle g_J, g_J \rangle / \alpha_{J-1} - \langle g_J, g_{J-1} \rangle / \alpha_{J-1} = C_J \langle g_{J-1}, g_{J-1} \rangle / \alpha_{J-1}$$

or,

$$C_J = \langle g_J, g_J \rangle / \langle g_{J-1}, g_{J-1} \rangle. \quad \blacksquare$$

As noted previously, the algorithm defined above, along with the Davidon-Fletcher-Powell method, are available as Fortran subroutines in Ref. 8.

2.2 Infinite-Dimensional Conjugate Gradient: Unconstrained

In this chapter the conjugate gradient method is treated separately in finite- and infinite-dimensional spaces because of applications. However, one could describe the method in a Hilbert space setting and, thus, cover both the finite- and infinite-dimensional cases in one development. Such is the approach taken in Refs. 15, 16, and 17.

The main references for Sections 2.2 and 2.3 are Refs. 6 and 18. In this section we shall consider problems which do not possess control or state variable inequality constraints; these will be included in the next section.

The infinite-dimensional problem which we are mainly concerned with is the following:

BASIC PROBLEM: Determine the control $u^*(t)$, $t \in [t_0, t_f]$, which minimizes:

$$J[u] = \tilde{\phi}(t_f, x_f) + \int_{t_0}^{t_f} L(t, x, u) dt \quad (2.25)$$

subject to:

$$\dot{x} = f(t, x, u) \quad , \quad x(t_0) = x_0 \quad (2.26)$$

$$\psi(t_f, x_f) = 0 \quad , \quad (p\text{-vector}; p \leq n + 1) \quad (2.27)$$

where x is an n -vector, u is an m -vector.

The algorithms in this report treat all of the terminal conditions (i. e., Eq. (2.27)) except one by the method of penalty functions; the remaining condition is employed as a stopping condition. Without loss of generality,

assume that

$$\psi(t_f, x_f) \equiv \begin{bmatrix} x_{1f}(t) - x_{1f} \\ \psi_2(t_f, x_{2f}, \dots, x_{nf}) \\ \cdot \\ \cdot \\ \psi_p(t_f, x_{2f}, \dots, x_{nf}) \end{bmatrix} = 0, \quad (2.28)$$

and that $x_1(t)$ is a variable which: (i) cannot reach the value x_{1f} until the terminal portion of the trajectory (e.g., a specified altitude or Mach number in reentry), (ii) will always be reached in a reasonable time, and (iii) will probably have a nonzero derivative at t_f . In this case, $x_1(t_f) = x_{1f}$ is a suitable stopping condition for the iterations.

Define

$$\phi(t_f, x_f) \equiv \tilde{\phi}(t_f, x_f) + \sum_{i=2}^p P_{i-1} \psi_i(t_f, x_f)^2, \quad (2.29)$$

where it is assumed, also, that $\tilde{\phi}(t_f, x_f)$ does not depend upon x_{1f} (this is the usual case in trajectory analysis; the assumption is not restrictive, however) and the

$$P_i > 0 \quad (i = 1, \dots, p-1) \quad (2.30)$$

are selected by the investigator. With the definitions (2.28) and (2.29) we have the following problem:

BASIC PROBLEM WITH PENALTY FUNCTIONS: Determine the control $u^*(t)$, $t \in [t_0, t_f]$, which minimizes

$$J[u] = \phi(t_f, x_f) + \int_{t_0}^{t_f} L(t, x, u) dt \quad (2.31)$$

subject to:

$$\begin{aligned} \dot{x} &= f(t, x, u), \quad x(t_0) = x_0 \\ x_1(t_f) &= x_{1f}. \end{aligned} \quad (2.32)$$

(Note: t_f is usually not specified.)

Before we list the formulas in the conjugate gradient method, we shall define a Hamiltonian function and adjoint variables which are useful in any function space iteration scheme. First, define

$$H \equiv L(t, x, u) + \lambda^T f(t, x, u), \quad (2.34)$$

where the n -vector $\lambda(t)$ will be characterized later. With this definition we have:

$$J[u] = \phi(t_f, x_f) + \int_{t_0}^{t_f} [H(t, x, u, \lambda) - \lambda^T \dot{x}] dt, \quad (2.35)$$

where the performance index (2.31) has been augmented to include $\int_{t_0}^{t_f} \lambda^T (f - \dot{x}) dt$.

Let $u^{(0)}(t)$ be an initial control estimate, and integrate $\dot{x} = f[t, x, u^{(0)}(t)]$ forward from $x(t_0) = x_0$ to form a corresponding trajectory, $x^{(0)}(t)$. Suppose there exists a vector $\lambda^{(0)}(t)$ and define

$$u^{(1)}(t) = u^{(0)}(t) + \delta u(t) \quad (2.36)$$

$$x^{(1)}(t) = x^{(0)}(t) + \delta x(t). \quad (2.37)$$

$$t_f^{(1)} = t_f^{(0)} + dt_f \quad (2.38)$$

Expand $J[u^{(1)}]$ about $J[u^{(0)}]$ to first-order:

$$\begin{aligned} J[u^{(1)}] &= J[u^{(0)}] + \phi_{t_f}^{(0)} dt_f + \sum_{i=2}^n \phi_{x_{if}}^{(0)} dx_{if} \\ &\quad + [H(t_f^{(0)}) - \lambda^{(0)T}(t_f^{(0)}) \dot{x}^{(0)}(t_f^{(0)})] dt_f \\ &\quad + \int_{t_0}^{t_f^{(0)}} [H_x^{(0)T} \delta x + H_u^{(0)T} \delta u - \lambda^{(0)T} \delta \dot{x}] dt. \end{aligned} \quad (2.39)$$

Integration by parts of the third term in the integrand gives

$$\begin{aligned} \Delta J[\delta u] &= J[u^{(1)}] - J[u^{(0)}] = (\phi_{t_f}^{(0)} + H_{t_f}^{(0)})_{t_f^{(0)}} dt_f - \lambda_1^{(0)}(t_f^{(0)}) dx_{1f} \\ &\quad + \sum_{i=2}^n (\phi_{x_{if}}^{(0)} - \lambda_i^{(0)}(t_f^{(0)}) dx_{if} \\ &\quad + \int_{t_0}^{t_f^{(0)}} [(H_x^{(0)} + \dot{\lambda}^{(0)})^T \delta x + H_u^{(0)T} \delta u] dt \end{aligned} \quad (2.40)$$

subject to:

$$dx_{if} = 0. \quad (2.41)$$

We now characterize $\lambda^{(0)}(t)$ so that a stable iterative algorithm is defined.

$$\text{SPECIFY: } \lambda_i^{(0)}(t_f^{(0)}) \equiv \phi_{x_{if}}^{(0)} \quad (i = 2, \dots, n) \quad (2.42)$$

$$\lambda_1^{(0)}(t_f^{(0)}) \equiv -(\phi_{t_f}^{(0)} + H^{(0)} + \sum_{i=2}^n \lambda_i^{(0)} \dot{x}_i^{(0)})_{t_f^{(0)}} / \dot{x}_1^{(0)}(t_f^{(0)}) \quad (2.43)$$

$$\dot{\lambda}^{(0)}(t) \equiv -H_x[t, x^{(0)}(t), u^{(0)}(t), \lambda^{(0)}(t)]. \quad (2.44)$$

Definitions (2.42), (2.43), (2.44) uniquely define the vector $\lambda^{(0)}(t)$ and it is formed by a backward integration.

Substitution of Eqs. (2.41)-(2.44) into Eq. (2.40) gives

$$\Delta J[\delta u] = \int_{t_0}^{t_f} H_u^{(0)T} \delta u dt. \quad (2.45)$$

The quantity $H_u^{(0)}(t)$ is the gradient in function space for this iteration, and the gradient method is defined by

$$u^{(J+1)}(t) = u^{(J)}(t) - \alpha_J H_u^{(J)}(t). \quad (2.46)$$

(Note that if $t_f^{(J+1)} > t_f^{(J)}$, then a scheme must be devised to define $u^{(J+1)}(t)$ on the interval $[t_f^{(J)}, t_f^{(J+1)}]$, but there are numerous ways of doing this.)

As with the parameter optimization problem, there exist numerous techniques which result in a stable method, e. g., one need only guarantee that the first-order expansion term dominate the expansion for $J[u^{(J+1)}]$ and that δu be chosen in such a way that

$$\int_{t_0}^{t_f} H_u^{(0)T}(t) \delta u(t) \leq 0. \quad (2.47)$$

In analogy with parameter optimization, a possible choice for δu is

$$\delta u^{(J)}(t) = -\alpha_J [H_u^{(J)}(t) + C_J p^{(J-1)}(t)], \quad (2.48)$$

where $\alpha_J > 0$ is the search parameter, $p^{(J-1)}(t)$ is the previous search direction with the property $\int_{t_0}^{t_f} H_u^{(J)T} p^{(J-1)} dt = 0$, and C_J is a constant to be defined. As shown in Ref. 6, the following function space conjugate gradient scheme satisfies these conditions:

UNCONSTRAINED CONJUGATE GRADIENT ALGORITHM

- 1) Guess $u^{(0)}(t)$ on $[t_0, t_f]$.
- 2) Compute:

$$\begin{aligned}
 & X^{(J)}(t), \lambda^{(J)}(t), H_u^{(J)}(t) \\
 & p^{(J)}(t) = H_u^{(J)}(t) + \frac{\int_{t_0}^{t_f} H_u^{(J)T} H_u^{(J)} dt}{\int_{t_0}^{t_f} H_u^{(J-1)T} H_u^{(J-1)} dt} p^{(J-1)}(t) \quad (2.49) \\
 & (p^{(0)}(t) \equiv H_u^{(0)}(t))
 \end{aligned}$$

- 3) Perform 1-D search to determine α_J in the formula

$$u^{(J+1)}(t) = u^{(J)}(t) - \alpha_J p^{(J)}(t). \quad (2.50)$$

- 4) Check on appropriate cutoff criterion (e. g., $\left| \frac{dJ}{d\alpha_J} \right|_{\alpha_J=0} \leq \epsilon$);
- 5) Return to 2).

In Eq. (2.49) above, the constant which multiplies $p^{(J-1)}$ may be written as

$$\langle H_u^{(J)}, H_u^{(J)} \rangle_1 / \langle H_u^{(J-1)}, H_u^{(J-1)} \rangle_1,$$

where

$$\langle a(t), b(t) \rangle_1 \equiv \int_{t_0}^{t_f} a(t)^T b(t) dt \quad (2.51)$$

is an inner product on the function space whereas

$$\langle a, b \rangle \equiv a^T b \quad (2.52)$$

is an inner product on R^n . Thus, the formula is the same as the finite-dimensional formula; one need only interpret properly the gradient and

inner product functions.

In Ref. 6, a few theorems concerned with the convergence of the function space conjugate gradient method are presented for both general functionals and functionals which result from linear-quadratic optimal control problems. For general functionals, the convergence theorem (which is only sufficient for convergence) essentially requires that one show that the second variation is "strongly positive" (i. e. , there exists a constant $M > 0$ such that for all admissible $u, \delta u$, $\delta^2 J(u; \delta u, \delta u) \geq M \|\delta u\|^2$).

As with parameter optimization, the quadratic case plays an important role in functional optimization; again, the argument being that when the solution is approached the general optimal control problem may be well-approximated by a linear-quadratic optimal control problem (formed by expanding the differential equations and boundary conditions to first-order, and the performance index to second-order). The theorems in Ref. 6 assume the resultant quadratic functional to be of the form

$$\Delta J = \langle \delta u, A \delta u \rangle_1, \quad (2.53)$$

where A is a positive definite, self-adjoint linear operator. Note that since δu is infinite-dimensional there is no reason to expect finite convergence even in a small neighborhood of the solution. (Of course, on a digital computer, one is really only interested in a good rate of convergence since problems are never converged to the limit.) Reference 7 shows how one may transform a class of linear-quadratic problems into the form of Eq. (2.53).

For the case of Eq. (2.53), Ref. 6 shows that the conjugate gradient method has certain desirable features which the classical gradient method does not possess. However, it has never been proved mathematically that the conjugate gradient step is better than the gradient step on every iterate. In fact the statement is probably untrue because of numerical experience which indicates that a gradient step every so often in a conjugate gradient algorithm (i. e. , a "reset" step) improves the convergence characteristics. Finally, as with general functionals, to show that the linear operator A in

Eq. (2.53) is positive definite usually requires a conjugate point test if the operator results from linearization of a nonlinear optimal control problem.

2.3 Infinite-Dimensional Conjugate Gradient: Constrained

In this section, the modifications of the Basic Problem With Penalty Functions (Eqs 2.31-2.33) and the Unconstrained Conjugate Gradient Algorithm to include state variable inequality constraints (SVIC) and control inequality constraints will be presented.

First, suppose that in addition to the equality constraints (2.32), (2.33), the problem contains the SVIC's:

$$S_i(t, x) \geq 0. \quad (i = 1, \dots, q) \quad (2.54)$$

There are two main ways of treating an SVIC:

- (i) Transform the problem into a multiple-arc problem with intermediate point equality constraints; this is the approach of Ref. 19.
- (ii) Augment the performance index to include the SVIC's by means of penalty functions; this is the approach of Ref. 1.

The main goal of the computer programs described in this report is to generate reasonable, near-optimal reentry trajectories with a minimal amount of guessing and analysis required of the user. The (i) approach above requires knowledge of the location and the number of times the inequality constraint boundary is encountered, which requires both analysis and additional programming by the user. Thus, the (ii) approach was chosen since this requires no additional programming and only the initial penalty coefficients must be estimated.

If the SVIC's (2.54) are present, then the performance index (2.31) is modified to

$$J[u] = \phi(t_f, x_f) + \int_{t_0}^{t_f} [L(t, x, u) + \sum_{i=1}^q S_i(t, x)^2 H_i(S_i)] dt, \quad (2.55)$$

where

$$H_i(S_i) = \begin{cases} C_i > 0 & \text{if } S_i < 0 \\ 0 & \text{if } S_i \geq 0 \end{cases}, \quad (2.56)$$

and the constant penalty coefficients C_i ($i = 1, \dots, q$) are selected by the investigator.

Second, suppose that inequality constraints

$$G_i(t, x, u) \geq 0 \quad (i = 1, \dots, r) \quad (2.57)$$

which satisfy the following constraint condition are present:

$$\begin{bmatrix} \frac{\partial G_1}{\partial u_1} & \dots & \frac{\partial G_1}{\partial u_m} & G_1 & 0 & \dots & 0 \\ \cdot & \cdot & \cdot & 0 & G_2 & \cdot & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \frac{\partial G_r}{\partial u_1} & \dots & \frac{\partial G_r}{\partial u_m} & 0 & 0 & \dots & G_r \end{bmatrix} \text{ has rank } r. \quad (2.58)$$

This condition is required to guarantee that the control may be determined from the appropriate $G_i = 0$ when a boundary is encountered. The condition is satisfied trivially if the constraints only contain control variables, e.g., $G = 1 - u^2 \geq 0$, and are independent.

Since the adjoint variables (or Lagrange multipliers) are continuous across corners where control boundaries are encountered, constraints of the form (2.57) may be treated directly with little modification of the program. Let us first describe the procedure for treating a constraint of the form (2.57) before we justify the method.

CONTROL CONSTRAINED CONJUGATE GRADIENT ALGORITHM

Suppose the control is a scalar and $|u| \leq 1$; the generalization to more than one control and other control constraints is straightforward:

- 1) At the beginning of the J^{th} iteration, we have a control $u^{(J)}(t)$, $J \in \{0, 1, 2, \dots\}$. Define $W_J \equiv \{t: |u^{(J)}(t)| = 1\}$, i.e., the set of points where $u^{(J)}(t)$ is on the boundary. Integrate forward $\dot{x} = f[t, x, u^{(J)}(t)]$ to the stopping condition and set $\lambda^{(J)}(t_f^{(J)})$.
- 2) Integrate $\dot{\lambda}^{(J)} = -H_x[t, x^{(J)}(t), \lambda^{(J)}, u^{(J)}(t)]$ backwards from $t_f^{(J)}$. Evaluate $H_u^{(J)}(t)$ in the usual way on $[t_0, t_f^{(J)}]$. However, the inner product $\langle H_u^{(J)}, H_u^{(J)} \rangle$ is defined by:

$$\langle H_u^{(J)}, H_u^{(J)} \rangle = \int_{[t_0, t_f] - W_J} H_u^{(J)^2} dt. \quad (2.59)$$

3) Perform the 1-D search with Eqs. (2.49), (2.50).

In the search, truncate $u^{(J+1)}$ at the boundary if $|u^{(J+1)}(t)| > 1$, i. e., for a trial α_J :

$$\text{if } u^{(J)}(t) - \alpha_J p^{(J)}(t) > 1, \text{ set } u^{(J+1)}(t) = 1 \quad (2.60)$$

$$\text{if } u^{(J)}(t) - \alpha_J p^{(J)}(t) < -1, \text{ set } u^{(J+1)}(t) = -1.$$

(This step gives us the means for adjusting the set W_J from iteration to iteration.) Return to (1) after α_J and W_{J+1} are determined.

Let us now justify the approach listed above; the method is developed in Ref. 18. The main difficulties in generating a method for treating control constraints are: (i) ensuring that the method is defined in such a way that it can converge to the true minimum (and not a false minimum), and (ii) developing a method consistent with (i) for defining $\langle H_u^{(J)}, H_u^{(J)} \rangle / \langle H_u^{(J-1)}, H_u^{(J-1)} \rangle$ when the iterate has bounded subarcs.

First, we shall consider how the algorithm should behave near the minimum. Suppose that the set W is known beforehand, i. e., the points $t \in [t_0, t_f]$ for which $u^*(t) = \pm 1$ are known. Then, the algorithm need only be concerned with "fine-tuning" the interior control segments. In this regard, we would want $H_u^{(J)}$ and $p^{(J)}$ to be such that it only changes the interior control segments and not the boundary segments. Thus, in the computation of the coefficient of $p^{(J-1)}(t)$ in Eq. (2.49), the effect of the boundary arcs is not included because of the form of Eq. (2.59), and this rule is consistent with requirement (i) above.

In reality, we do not know the set W beforehand, so we must devise a mechanism for the sets W_J to change from iterate to iterate and such that $W_J \rightarrow W$. This is accomplished by Step (3) of the procedure defined above; that is, the set W_J is modified in the 1-D search.

CHAPTER 3

PHASE I PROGRAM

3.1 Basic Description

The Phase I Program is designed to minimize a weighted performance index which includes the following effects:

- i. Crossrange
- ii. Downrange
- iii. Aerodynamic loading
- iv. Terminal total heat
- v. Terminal altitude

The equations of motion are written in a cartesian coordinate system defined by:

$$\hat{I} = \frac{\bar{r}}{|\bar{r}|}$$

$$\hat{K} = \frac{\bar{r} \times \bar{V}}{|\bar{r} \times \bar{V}|}$$

$$\hat{J} = \hat{K} \times \hat{I}$$

The Aerodynamic Angles are defined by the following coordinate system:

$$\hat{i}_p = \frac{\bar{r} \times \bar{V}_R}{|\bar{r} \times \bar{V}_R|} \quad \hat{i}_q = \hat{i}_p \times \frac{\bar{V}_R}{V_R}$$

$$d_1 = \frac{\bar{u}}{|\bar{u}|} \cdot \frac{\bar{V}_R}{V_R}, \quad d_2 = \frac{\bar{u}}{|\bar{u}|} \cdot \hat{i}_q, \quad d_3 = \frac{\bar{u}}{|\bar{u}|} \cdot \hat{i}_p$$

$$\tan \alpha = \frac{d_2}{d_1}, \quad \tan \beta = \frac{d_3}{d_1}, \quad \tan \alpha_t = \frac{\sqrt{d_2^2 + d_3^2}}{d_1}$$

The state equations are²⁰:

$$\dot{\bar{r}} = \bar{V}$$

$$\dot{\bar{V}} = -\frac{\mu}{|\bar{r}|^3} \bar{r} + \rho A |V_R|^2 C_{L_\alpha} \left[-\left(\frac{C_A}{C_{L_\alpha}} + 2\eta \right) \frac{\bar{V}_R}{V_R} + \left[1 + (2\eta - 1) \frac{\bar{V}_R \bar{V}_R^T}{V_R} \right] \frac{\bar{u}}{|\bar{u}|} \right]$$

$$\dot{Q} = C_q \rho^{\frac{1}{2}} V_R^{3.15}$$

$$\bar{V}_R = \bar{V} - \bar{V}_A$$

where $\bar{V}_A \equiv$ inertial velocity of the atmosphere. The equations involve the following assumptions:

- The relative velocity vector \bar{V}_R is in the plane of the vehicle that produces the greatest lift.
- No aerodynamic moments exist about the center of mass.

The performance index is

$$J = C_1 r_c + C_2 r_d + P_1 (h - \bar{h}_f)_{t_f}^2 + P_2 (Q)_{t_f}^2 + P_4 \int_{t_0}^{t_f} \left(\frac{L^2 + D^2}{m^2} - 9g^2 \right) \cdot U \left(\frac{L^2 + D^2}{m^2} - 9g^2 \right) dt$$

where

r_c = cross range

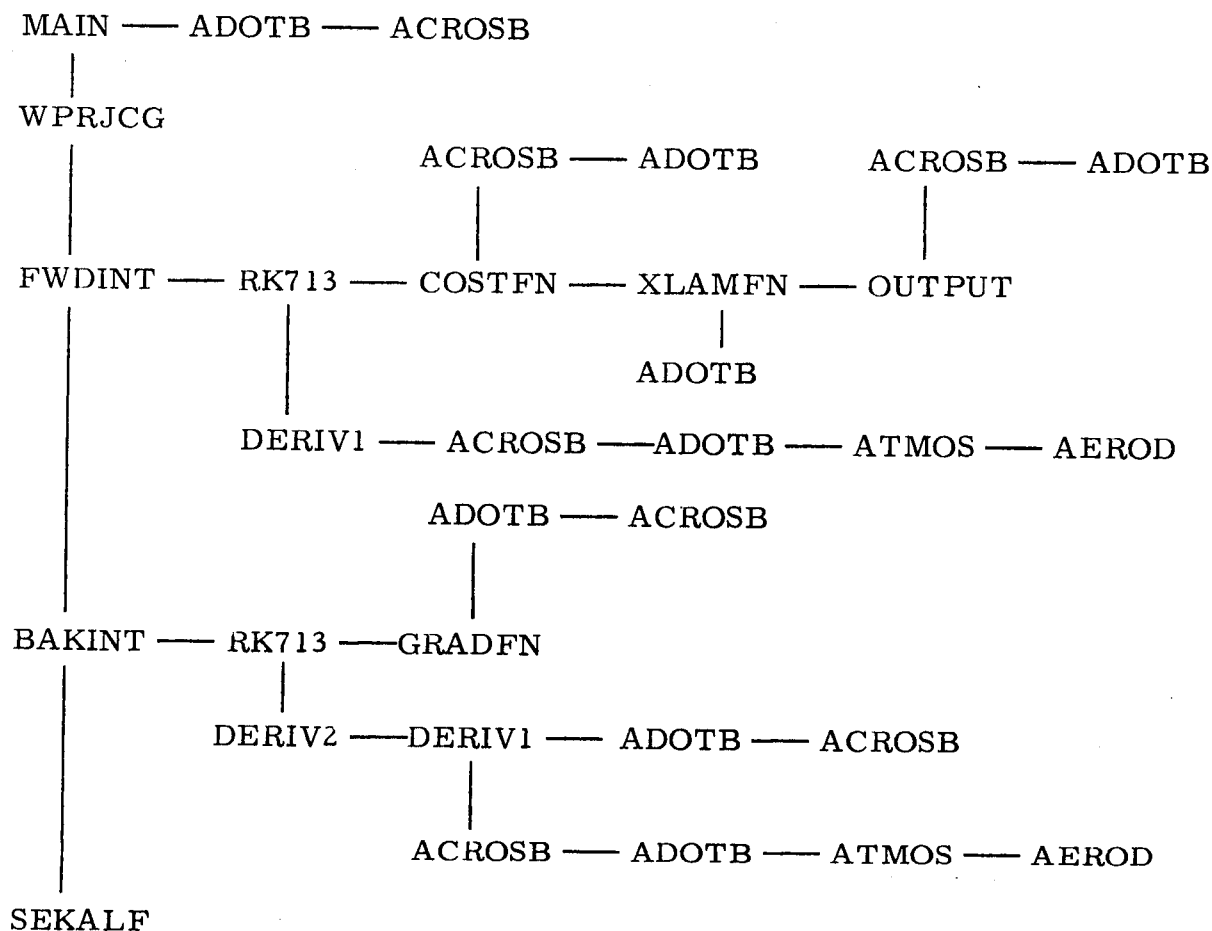

r_d = down range

$$U(\cdot) = \begin{cases} 1 & \text{if } (\cdot) > 0 \\ 0 & \text{if } (\cdot) \leq 0 \end{cases}$$

The Hamiltonian is

$$H = \lambda_{\mathbf{r}} \dot{\mathbf{r}} + \lambda_{\mathbf{V}} \dot{\mathbf{V}} + \lambda_{\mathbf{Q}} \dot{\mathbf{Q}} + P_4 \left(\frac{L^2 + D^2}{m^2} - 9g^2 \right) \cdot U \left(\frac{L^2 + D^2}{m^2} - 9g^2 \right)$$

3.2 Subroutine Map

3.3 Subroutine Descriptions

MAIN: Reads in all necessary data, sets integration coefficients, computes initial values, and calls on the conjugate gradient subroutine (WPRJCG). On Return, MAIN prints out a message concerning the results of the iteration and prints out the control obtained by that iteration.

A. Namelist Input Data

PI = π

RE = earth's radius

XMU = μ , gravitational constant

OMEGE(3) = angular velocity of the earth

AREA = aerodynamic reference area

ECOEF = heating coefficient

XO(3) = initial position vector

VO(3) = initial velocity vector

TO = initial time

ALTF = desired final altitude

XMACH = desired final Mach number

FLTANG = desired final flight path angle

QMAX = desired final heating value

XMASS = vehicle mass

IOUT = print frequency for forward integration

IOUT2 = print frequency for backward integration

IPRINT1 = print control flag

IPRINT2 = print control flag

DELTS = integration stepsize

IKEY = call flag for output (see FWDINT)

ERRMX = error tolerance for integration routine

ERRMN = not used

TCUT = upper time limit on trajectory

EPST = cutoff tolerance for norm of control change

EPSTF = not used

EPSA = cutoff tolerance for integration altitude cutoff

EPSIT = cutoff tolerance on gradient norm
 ERR = cutoff tolerance for small cost change
 ITMAX = limit on number of conjugate gradient iterations
 ITMX = limit on steps in 1-D search
 KOUNTM = limit on iterations for altitude cutoff
 CSTR = guess of final cost value
 B = control bound (see SEKALF)
 PFUN(4) = penalty coefficient vector
 CCOST(2) = coefficients in cost functional
 DTFM = maximum allowable final time change
 XDTFM = fraction of DTFM used to start 1-D search

B. Control Vector Data

IJKU = total number of control points
 U(IJKU,4) = control vector and time point

WPRJCG: This subroutine controls the application of the conjugate gradient algorithm. It calls the forward and backward integration routines, directs the one dimensional search, and updates the control vector and terminal time. It checks for algorithm termination on small cost change, total number of iterations, errors in the 1-D search, failure to generate an admissible trajectory on the first trial.

SEKALF (One-Dimensional Search Subroutine): Determines the parameters for the new control value in the conjugate gradient algorithm. Fits a cubic in α to known values of $J(\alpha)$, $\partial J / \partial \alpha$, to obtain $\min J(\alpha)$ and then α^* for J min.

FWDINT: Subroutine performs the forward integration of the state variables and calls the subroutines to evaluate the cost functional and final multiplier values.

RK713: 7th Order Runge-Kutta integration scheme called by both FWDINT and BAKINT.

BAKIWT: Subroutine performs the backward integration of the state variables and multiplier equations, and calls on GRADFW to calculate the

gradients and store the value at each integration step. The subroutine also determines the new search direction.

DERIV1: Subroutine which calculates the time derivatives of the state variables.

DERIV2: Subroutine which calculates the time derivatives of the multipliers.

ATMOS: Calculates atmospheric parameters.

AEROD: Calculates aerodynamic parameters.

XLAMFN: Computes final multiplier values.

COSTFN: Computes cost functional.

OUTPUT: Subroutine called by FWDINT which prints out desired trajectory data.

3.4 Phase II Program Notes

- i) The program obtains the state for the multiplier equations by integrating the state backward from the terminal conditions of the forward state integration (as opposed to storing the state in the forward integration).
- ii) Each iterate is terminated on an assumed t_f , which is part of the iteration procedure. The value of t_f for the base trajectory is determined by the trajectory as the time when the desired altitude is reached (thus, the program also has an altitude-cutoff capability).
- iii) See Appendix A for a listing of the Phase I Program.

CHAPTER 4

PHASE II PROGRAM

4.1 Basic Description

The Phase II Program is designed to minimize a performance index which includes the following effects:

1. Crossrange
2. Downrange
3. Total heat
4. Peak heating rate
5. Final speed and flight path angle boundary conditions.

Phase II Program uses a nonrotating earth centered spherical coordinate system with an Euler angle body-axis system to define the aerodynamic forces.

The equations of motion assuming a nonrotating earth and no aerodynamic moments are

$$\dot{R} = V \sin \gamma$$

$$\dot{\theta} = \frac{V \cos \gamma \cos \psi}{R \cos \phi}$$

$$\dot{\phi} = \frac{V \cos \gamma \sin \psi}{R}$$

$$\dot{V} = -\frac{\mu \sin \gamma}{R^2} - \frac{D}{m}$$

$$\dot{\gamma} = -\frac{\mu \cos \gamma}{R^2 V} + \frac{V \cos \gamma}{R} + \frac{L}{mV} \cos \beta$$

$$\dot{\psi} = \left[-\frac{V \cos \gamma \cos \psi \sin \phi}{R \cos \phi} - \frac{L \sin \beta}{mV \cos \gamma} \right]$$

where the drag (D) and lift (L) are defined by

$$L = \frac{1}{2} \rho S V^2 C_L(\alpha, M)$$

$$D = \frac{1}{2} \rho S V^2 C_D(\alpha, M)$$

The cost functional to be minimized is:

$$J = C(1) R_e \phi_f^2 + C(2) R_e \theta_f^2 + C(3) (V(t_f) - \bar{V}_f)^2 + C(4) [\gamma(t_f) - \bar{\gamma}_f]^2 \\ + C(5) \int_{t_0}^{t_f} \dot{q} dt + C(6) \int_{t_0}^{t_f} \ddot{q}^2 dt$$

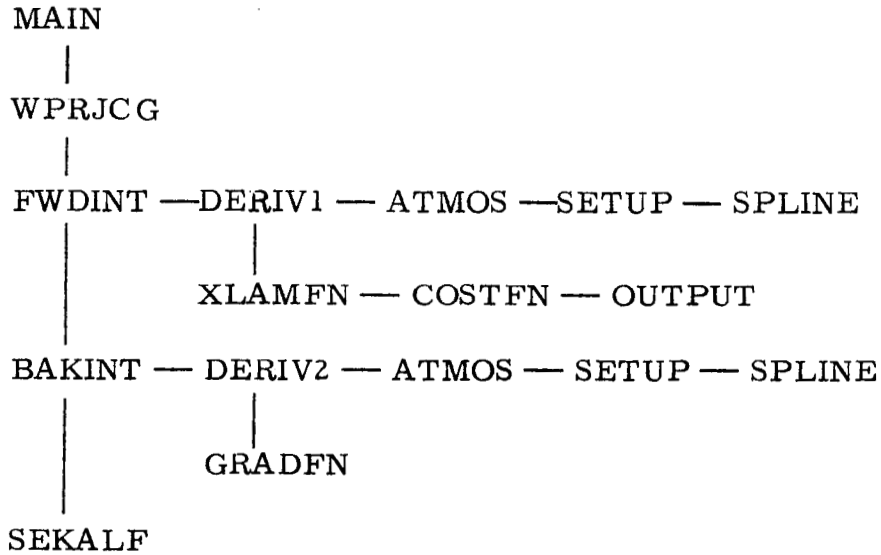

The term $\int_{t_0}^{t_f} \ddot{q}^2 dt$ is an approximate method for minimizing the peak heat rate.

The Hamiltonian is

$$H = C(5) \dot{q}(R, V) + C(6) \ddot{q}^2(R, V, \gamma) + \lambda_1 (V \sin \gamma) \\ + \lambda_2 \left(\frac{V \cos \gamma \cos \psi}{R \cos \phi} \right) + \lambda_3 \left(\frac{V \cos \gamma \sin \psi}{R} \right) \\ + \lambda_4 \left(-\frac{\mu \sin \gamma}{R^2} - \frac{D}{m} \right) + \lambda_5 \left(-\frac{\mu \cos \gamma}{R^2 V} + \frac{V \cos \gamma}{R} + \frac{L}{mV} \cos \beta \right) \\ + \lambda_6 \left(-\frac{V \cos \gamma \cos \psi \sin \phi}{R \cos \phi} - \frac{L \sin \beta}{mV \cos \gamma} \right)$$

Forward integration of the state variables is cutoff on a desired altitude.

4.2 Subroutine Map

4.3 Subroutine Descriptions

MAIN: Reads in all necessary input parameters, sets up spline interpolation of aerodynamic coefficients and calls the conjugate gradient subroutine WPRJCG. On Return, MAIN prints out message concerning the results of the iteration and prints out the control obtained by that iteration.

SETUP - SPLINE - Subroutine computes aerodynamic coefficients based upon piecewise cubic spline interpolation. Input is angle of attack (α) and Mach number (M); returned are the values of $C_L, C_D, \partial C_L / \partial M, \partial C_D / \partial M, \partial C_D / \partial \alpha$.

(For test runs the aerodynamics were approximated by:

$$C_D = 2.2 \sin^3 \alpha + .08$$

$$C_L = 2.2 \sin^2 \alpha \cos \alpha + .01.)$$

4.4 Phase II Program Notes

- i) The state values for the backward integration of the multiplier equations are stored during the forward integration (as opposed to backward integration for the state). The program currently can store the state at 999 time points.
- ii) All trajectories terminate at a specified, desired altitude. The modification to the transversality conditions is discussed in Chapter 2. Since the terminal time of the $N + 1$ trajectory, say $t_f^{(N+1)}$, may be larger than $t_f^{(N)}$ (since h_f is the cutoff condition), a linear extrapolation of the control is used on $[t_f^{(N)}, t_f^{(N+1)}]$.
- iii) See Appendix B for a listing of the Phase II Program.

CHAPTER 5

CONCLUSIONS AND RECOMMENDATIONS

5.1 Summary

Two computer programs for shuttle reentry optimization have been developed. The programs make extensive use of subroutines so that they may be adapted to other atmospheric optimization problems with little difficulty. Because of contract budget restrictions and the long flight times of realistic shuttle reentry trajectories, the programs have only been checked out with respect to programming errors. In the next section, suggestions for a study of the convergence properties of the programs will be presented. Also, our limited experience obtained with the programs will be discussed. However, with respect to these comments, it should be remembered that no controlled study was performed, and thus, the comments are somewhat tenuous.

5.2 Conclusions and Recommendations

1. Before an extensive analysis of the optimization of reentry trajectories is undertaken, it is recommended that a carefully controlled study of numerical integration procedures be performed for reentry problems in which: (a) the controls are piecewise linear (or possibly higher-order splines) in an integration step, (b) the aerodynamic data is given in tabular form, and (c) the vehicle is a relatively low-drag vehicle (e.g., the high-crossrange shuttle). Much of our time was devoted to determining an acceptable numerical integration package while the optimization procedure was the major goal of the study. We found that RK 7-13 was an excellent scheme with constant aerodynamics and smooth controls; however, with piecewise linear controls and spline-fit aerodynamics, its performance was reduced substantially. For this reason, a fourth-order, predictor-corrector scheme with fixed stepsize is employed in the Phase II-Program. Research should be conducted to make the problem suitable for use with RK 7-13 (or some other high-order scheme) to shorten the long integration times.
2. Because of the relatively low-drag characteristics of the

high-crossrange shuttle, arbitrary initial estimates of the controls in any optimization program may cause highly oscillatory trajectories. This is due to the fact that the path angle may become positive (positive path angle is above the local horizontal) and oscillate about zero degrees. Thus, it is recommended that, if possible, initial control estimates be chosen so that γ remains negative. Some investigators have used artificial means to insure $\gamma \leq 0$, e.g., impose a state variable inequality constraint, add damping to the initial iterates, increase the drag in the initial iterates. This problem may be accentuated by an inaccurate numerical integration scheme because $\dot{\gamma}$ is essentially the difference between two terms of the same order of magnitude. Thus, $\dot{\gamma}$ may become positive because of numerical error when its true physical value is negative.

3. Neither program uses nondimensional variables. If the rate of convergence is slow in simulations, nondimensionalization of the variables may improve the rate.

4. Most of the investigations which have applied the conjugate gradient method to optimal control problems have been of low-dimension, near-linear, and fixed final time. Two exceptions are Refs. 21 and 22. In these studies, it was found that the method did not perform satisfactorily on a problem with tight terminal conditions²¹ and a free-final time problem²². Since the two programs of this report treat the free final time problem in two different ways, trends as to which method is best would be useful information.

5. In the Phase II-Program, $\int_{t_0}^{t_f} \dot{q}^2 dt$ is used in the performance index to penalize large heat rate slopes, and, thus, should aid in "flattening-out" the heating rate. This conjecture should be tested since if it serves to flatten the peak heating rate, it might be a simple way of controlling peak heating rate in an on-board, optimization oriented guidance scheme.

6. A convenient test problem for reentry is the maximum crossrange

problem. In this problem, the optimal control should consist of an angle of attack which causes $(L/D)_{\max}$ and a bank angle which is initially near 90° and which decreases (nearly linearly) toward 0° as time increases to t_f . In our limited testing of the Phase II-Program on the IBM 360/67, a typical iterate (including the 1-D search) required about one minute of CPU time for a double precision, 2000 second (real-time) trajectory with a fixed stepsize of four seconds.

7. As noted above, a typical iterate requires approximately one minute of CPU time. Of course, the large amount of computer time is mainly due to the numerical integration requirements. Hopefully, more efficient numerical integration schemes will be developed for use in conjunction with function-space gradient-type algorithms. In this development one should keep in mind that both forward and backward integrations are required, and this heavily influences the choice of a variable stepsize integration scheme. A possibility in this direction is spline numerical integration schemes since they result in "global" information as opposed to discrete data.

APPENDIX B

LISTING OF PHASE II PROGRAM

NOTE: The Phase II Program is built to use either single aerodynamic approximations or spline-fit aerodynamics. Both listings are presented in this Appendix. To use the simple aerodynamic approximations, use the listing of pages 68-90; to use the spline-fit aerodynamics replace MAIN, DERIV1, and DERIV2 by the listings on pages 91-98 and add the subroutine SETUP (pages 93-94).
